

The Pliocene Paradox (Mechanisms for a Permanent El Niño)

A. V. Fedorov,^{1*} P. S. Dekens,^{2†} M. McCarthy,² A. C. Ravelo,² P. B. deMenocal,³ M. Barreiro,⁴ R. C. Pacanowski,⁵ S. G. Philander⁴

During the early Pliocene, 5 to 3 million years ago, globally averaged temperatures were substantially higher than they are today, even though the external factors that determine climate were essentially the same. In the tropics, El Niño was continual (or “permanent”) rather than intermittent. The appearance of northern continental glaciers, and of cold surface waters in oceanic upwelling zones in low latitudes (both coastal and equatorial), signaled the termination of those warm climate conditions and the end of permanent El Niño. This led to the amplification of obliquity (but not precession) cycles in equatorial sea surface temperatures and in global ice volume, with the former leading the latter by several thousand years. A possible explanation is that the gradual shoaling of the oceanic thermocline reached a threshold around 3 million years ago, when the winds started bringing cold waters to the surface in low latitudes. This introduced feedbacks involving ocean-atmosphere interactions that, along with ice-albedo feedbacks, amplified obliquity cycles. A future melting of glaciers, changes in the hydrological cycle, and a deepening of the thermocline could restore the warm conditions of the early Pliocene.

The early Pliocene was similar to and also very different from the world of today. The intensity of sunlight incident on Earth, the global geography, and the atmospheric concentration of carbon dioxide (I) were close to what they are today, but surface temperatures in polar regions were so much higher that continental glaciers were absent from the Northern Hemisphere, and sea level was ~ 25 m higher than today (2–5). This apparent paradox—that conditions today and those during the early Pliocene are two different climate states in response to practically the same external forcing—can be addressed with information from such sources as the Pliocene Research Interpretations and Synoptic Mapping Project (PRISM) (2). Although there are some inconsistencies in the information concerning tropical ocean temperatures (6), most of the discrepancies can be eliminated by considering Pliocene observations in the broader context of earlier and subsequent climate changes, rather than in isolation.

Over the past 65 million years, since the beginning of the Cenozoic when temperatures in polar regions were in the neighborhood of 10°C , Earth experienced erratic global cooling (Fig. 1A). This was a consequence primarily of the drifting of the continents, accompanied by changes in ocean-basin geometry, mountain

building, volcanic eruptions, and other phenomena that affect the two factors that determine globally averaged surface temperatures: the

albedo of the planet and the atmospheric concentration of greenhouse gases. Superimposed on the global cooling were periodic climate cycles in response to Milankovitch forcing. This term refers to modest, periodic variations in the distribution of sunlight because of periodic variations in orbital parameters such as the angle of tilt (obliquity) of Earth’s axis.

The response to Milankovitch forcing involves not only glaciers that wax and wane, but also tropical sea surface temperatures (SSTs) that rise and fall (7–10). These phenomena could be separate to some degree, each involving its own physical processes and feedbacks, in the same way that the response to seasonal variations in sunlight involves several different phenomena such as the Indian monsoons, coastal upwelling off southwest Africa, and severe winter storms in central Canada. In other words, an explanation for the monsoons does not explain the other features of the seasonal cycle. It is similarly unlikely that processes involving ice sheets alone can explain all aspects of the response to Milankovitch forcing. The important additional processes are likely to include biogeochemical cycles such as the carbon cycle, as well as tropical ocean-atmosphere interactions.

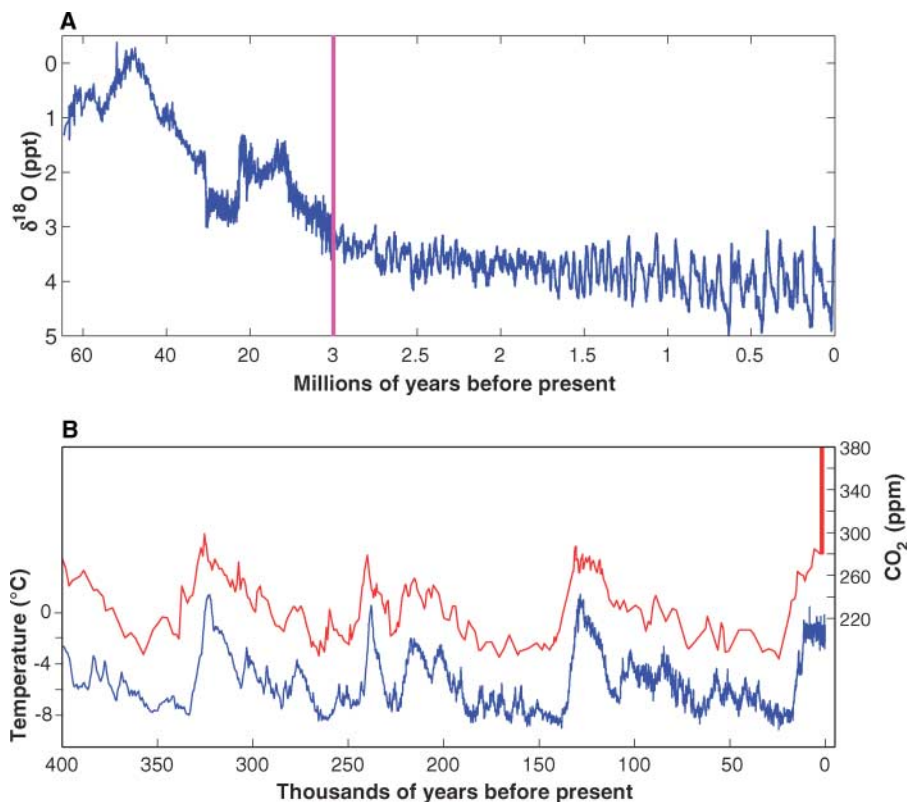

Fig. 1. (A) Variations in $\delta^{18}\text{O}$ over the past 60 million years. Higher values of $\delta^{18}\text{O}$ indicate colder climate (greater global ice volume). The gradual cooling over the past ~ 50 million years is evident. Note that the time scale changes at 3 Ma. The Milankovitch cycles are modest in amplitude up to ~ 3 Ma but then start amplifying (23). (B) Fluctuations in temperature and in the atmospheric concentration of carbon dioxide over the past 400,000 years as inferred from Antarctic ice-core records (45). The vertical red bar is the increase in atmospheric carbon dioxide levels over the past two centuries and before 2006.

†These authors contributed equally to this work.

Although Milankovitch forcing has been relatively constant over the past several million years, the amplitude of the climatic response underwent remarkable changes as the long-term global cooling introduced different climate feedbacks. The Pliocene is of special interest because the feedbacks that came into play during that epoch, around 3 million years ago (Ma), started an amplification of the response of climate to orbital forcing. Over the past ~1 million years, this process culminated in drastic oscillations between prolonged glaciations, or ice ages, and brief, warm interglacials (Fig. 1). During the warm interglacial periods—including the current one, which began some 10,000 years ago—conditions approach those of the early Pliocene. Will the present warm conditions terminate soon, to be followed by the next ice age? Or will the onset of the next ice age be inhibited by the current rise in the atmospheric concentration of greenhouse gases induced by humans (Fig. 1B)? Will that rise restore the warm conditions of the early Pliocene? Answers to these questions require identification of the processes that maintained warm conditions in the early Pliocene and then terminated them. Many studies focus on high-latitude processes associated with the appearance of northern continental ice sheets at ~3 Ma. More recently, attention has turned to the tropics after the discovery that El Niño was a continual (rather than intermittent) phenomenon up to ~3 Ma (6, 11, 12).

A Polar Perspective

The global cooling that started around 50 Ma led to the appearance of large ice sheets, first on Antarctica around 35 Ma and subsequently on northern continents at ~3 Ma (13). In sediments from a site in the North Pacific Ocean, ice-rafted debris appears abruptly at ~2.7 Ma, indicating that the warm conditions of the early Pliocene had come to an end (14). Did this happen because of the increase in Earth's albedo when Northern Hemisphere ice sheets appeared?

This hypothesis has been tested with the use of general circulation models (GCMs) of the atmosphere. The results indicate that removal of the northern ice sheets increases temperatures only in the regions initially covered with ice (4). If, in addition, SSTs are specified to be high in high latitudes but unchanged in

low latitudes, then the atmosphere is warmer over much larger regions, with some effects extending into the tropics (15).

These results suggest that high SSTs in high latitudes, more than low albedo, helped maintain the warm conditions of the early Pliocene, but what processes maintained those high SSTs? One possibility is a larger poleward transport of heat by oceanic currents during the early Pliocene. Presumably the closure of the Panamanian Seaway in the early Pliocene reorganized the oceanic circulation and ultimately altered the poleward transport of heat. However, an open Panamanian Seaway could not explain the early Pliocene high-latitude warmth because the closure at the end of the warm period would have intensified the deep, thermohaline circulation in the Atlantic sector (16, 17), thus transporting more, not less, heat northward. It is conceivable that what mattered most was the northward transport not of heat, but of moisture

that promoted the growth of the glaciers and hence a cooling trend (18). One problem with this argument is that the timing of the closure between 4.5 and 4.0 Ma (19) was much earlier than the onset of cold high-latitude conditions. Furthermore, this still leaves the warm conditions of the early Pliocene unexplained.

Another puzzle concerns the amplification of the Milankovitch cycles that started around 3 Ma. At high latitudes, the appearance of northern glaciers at that time introduced ice-albedo feedbacks that could have caused the amplification. Those feedbacks depend on variations in the intensity of solar radiation at high latitudes in summer (13). The precession of the equinox and changes in Earth's obliquity make comparable contributions to high-latitude summer solar radiation. Why then, in the global ice volume records (Fig. 1), is the obliquity signal dominant over the precession signal (13)?

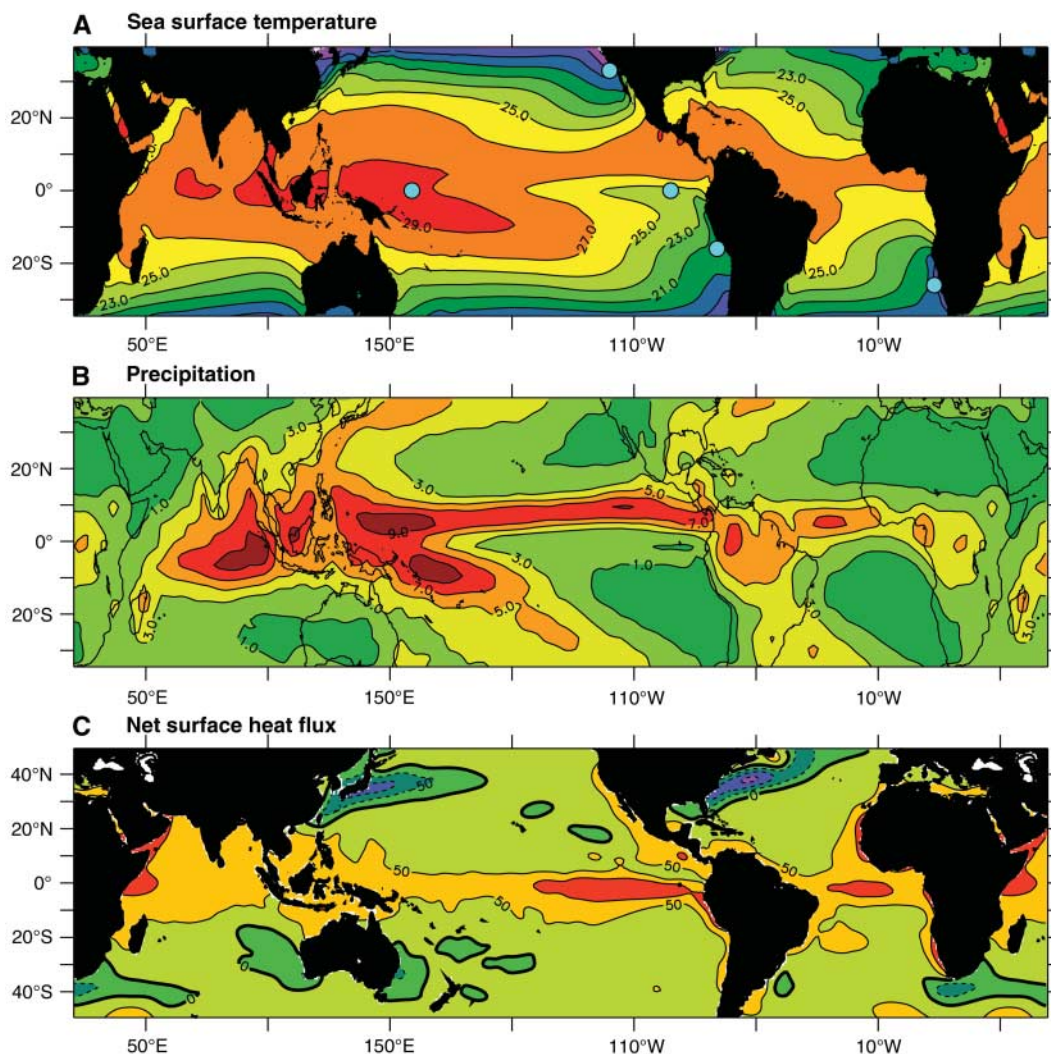

Fig. 2. (A) Annual mean SST pattern ($^{\circ}\text{C}$). The dots show approximate locations of the deep cores used to calculate the time series of SSTs displayed in Fig. 3. (B) Annual mean rainfall pattern (mm/day). Note the maximum in precipitation in the tropics associated with the ITCZ. (C) Annual mean heat flux (W/m^2) into the ocean at low latitudes and out of the ocean at higher latitudes (46). The contour interval is $50 \text{ W}/\text{m}^2$. Note a slightly different latitudinal extent of (C) as compared to (A) and (B).

Variation in the equator-to-pole gradient of solar heating is dominantly controlled by obliquity. This gradient becomes a key parameter if the focus is not on the poleward transport of heat, which involves a negative feedback, but instead on the transport of moisture from low latitudes, which can amplify the waxing and waning of ice sheets (20). This argument brings conditions in the tropics into play but cannot explain recent findings that Milankovitch cycles of both ice volume and equatorial Pacific SSTs became amplified around 3 Ma. Obliquity stands out as the dominant signal, with the SST changes leading those in ice volume by several thousand years (7, 21). Even if ice-albedo feedbacks came into play before changes in ice volume, how could they have caused variations in the tropics? What are the tropical processes that could have contributed to climate variations associated with ice ages?

Tropical Perspective

Previous studies based on sparse data suggested that tropical and subtropical SSTs during the early Pliocene were essentially the same as those of today (2). Recent data from regions not covered by PRISM indicate otherwise. Apparently the salient features of SST patterns in low latitudes—the cold surface waters off the western coasts of Africa and the Americas (Fig. 2)—were absent until ~3 Ma. This is evident in Fig. 3, which shows that up to ~3 Ma, the SST difference between the eastern and western equatorial Pacific was very small, and cold surface waters were absent from the coastal upwelling zones off the western coasts of Africa and the Americas (11, 12, 22–24). Today, a large reduction in the east-west temperature gradient along the equator in the Pacific occurs only briefly during El Niño, which in effect was continual rather than intermittent up to 3 Ma. Corroborating evidence for a continual (or “permanent”) El Niño is available in land records (25) that document the distinctive regional climate signatures associated with El Niño. Up to 3 Ma there was a persistence of mild winters in central Canada and the northeastern United States, droughts in Indonesia, and torrential rains along the coasts of California and Peru and in eastern equatorial Africa. The onset of dry conditions in the latter region around 3 Ma may have been important in the evolution of African hominids (26, 27).

Persistent El Niño conditions would have had a huge impact on the global climate, given

Fig. 3. (Top) SST records in the western equatorial Pacific (red line, ODP site 806) and in the eastern equatorial Pacific (blue line, site 847), both based on Mg/Ca and adapted from (11), and that for the eastern Pacific based on alkenones (green dots, site 847) and adapted from (24). Larger circles are for the data based on Mg/Ca but from (44) for ODP sites 806 (red) and 847 (blue). Pink shading denotes the early Pliocene. For discussion, see (6). (Bottom) Alkenone-based SST records for the California margin (black, ODP site 1014) (24), the Peru margin (blue, site 1237) (24), and the West African margin (green, site 1084) (22). The locations of the ODP sites are shown in Fig. 2; for the exact geographical locations, see (47).

that today even brief El Niño episodes can have a large influence. The reasons are evident in Fig. 2, which shows a remarkably high correlation between tropical SSTs and rainfall patterns. Tall, rain-bearing, convective clouds cover the warmest waters, but highly reflective stratus decks that produce little rain cover the cold waters. During El Niño, the warming of the eastern equatorial Pacific reduces the area covered by stratus clouds, thus decreasing the albedo of the planet, while the atmospheric concentration of water vapor—a powerful greenhouse gas—increases. Calculations with a GCM of the atmosphere indicate that this happened during the early Pliocene and contributed significantly to the warm conditions at that time (28).

The appearance of cold surface waters around 3 Ma in regions remote from each other (Figs. 2 and 3A) can be explained in terms of a global shoaling of the oceanic thermocline. [A contributing factor could have been the northward drift of Australia that restricted flow from the equatorial western Pacific into the Indian Ocean (29).] A shallower thermocline must involve changes in the oceanic heat budget shown in Fig. 2 (30, 31). In a state of equilibrium, the loss of heat in high latitudes—mainly where cold continental air masses flow over the warm Gulf Stream and Kuroshio Current in winter—balances the gain, mostly in low-latitude upwelling regions where cold water rises to the surface.

An increase in the loss of heat in high latitudes must be accompanied by an increase in the gain of heat, which requires a shallower equatorial thermocline (30). A decrease in the heat loss, and associated reduction in the poleward heat transport by the ocean, would imply a deeper equatorial thermocline.

The oceanic heat transport is affected by the meridional overturning of the oceanic circulation. A freshening of the surface waters in the extratropics, which reduces the surface meridional density gradient between low and high latitudes, can reduce the heat transport. This is true for the deep, slow thermohaline component of the circulation whose changes affect mainly the climate of the northern Atlantic (32), as well as for the rapid, shallow wind-driven component whose changes affect mostly the tropics. Sufficiently large freshening in the extratropics can induce a perennial El Niño (33).

Idealized calculations with an ocean GCM (Fig. 4) show that such a freshening can reduce the zonal SST gradient along the equator, reduce the poleward heat transport, and deepen the equatorial thermocline (33). As the freshwater flux increases from one experiment to the next, the different parameters are seen to change slowly at first and then to change rapidly as the flux approaches a critical value. When the freshwater forcing exceeds a threshold, the zonal SST gradient vanishes and permanently warm conditions prevail in the

tropics. Thus, these calculations represent one potential mechanism for maintaining a permanent El Niño.

Our arguments suggest that, during (and probably before) the early Pliocene, when El Niño was continual, oceanic heat gain at low latitudes and heat loss at high latitudes were minimal, and the thermocline was deep. The theory that the gradual global cooling during much of the Cenozoic (Fig. 1) and the associated decrease in the temperature of the deep ocean (34) caused the thermocline to shoal has corroborating evidence (11). A threshold was reached around 3 Ma when the thermocline became so shallow that the winds could bring cold waters to the surface in the various upwelling zones (31). With the transition to this colder climate, the mean SSTs in the eastern equatorial Pacific should have become asymmetric with respect to the equator, possibly resembling the present-day structure in which warmer water and the Intertropical Convergence Zone (ITCZ) stay north of the equator while colder water stays south of it (Fig. 2B).

The appearance of cold surface waters in the equatorial upwelling zones introduced feedbacks that affected the response of tropical SSTs to Milankovitch forcing. The winds influence SSTs and also depend on those temperatures because they blow from the cold toward the warm regions along the equator where the Coriolis force vanishes. This circular argument implies a positive feedback between the ocean and the atmosphere first described by Jacob Bjerknes (35). (Another positive feedback involves low stratus clouds.) In the case of El Niño, the SST-wind feedback depends on an adiabatic redistribution of warm surface waters (Fig. 5A). On much longer time scales it involves diabatic, vertical movements of the thermocline (Fig. 5B) and influences the climatic response to obliquity variations (31). During times when obliquity and solar heating in high latitudes have maxima, reduced oceanic heat loss to the atmosphere can induce a deepening of the equatorial thermocline and a tendency toward El Niño conditions. This is possible only on time scales sufficiently long for the tropical oceans to adjust to changes in higher latitudes.

Obliquity causes annually averaged sunlight to vary for such prolonged periods (thousands of years) that the tropical response is practically

in phase with the extratropical forcing (7). The precession of the equinox, by contrast, has too short a time scale for an adjustment in the oceanic heat budget to be possible. It induces seasonal changes in sunlight but has no effect on the annually averaged sunlight. These arguments explain why tropical Pacific temperature records are dominated by obliquity variations and are nearly in phase with high-latitude rather than local solar variations (21, 31), and why

Pacific; it contributed to global warming by causing the absence of stratus clouds from the eastern equatorial Pacific, thus lowering the planetary albedo, and by increasing the atmospheric concentration of water vapor, a powerful greenhouse gas. Today the atmospheric concentration of another greenhouse gas, carbon dioxide, is comparable to what it was in the early Pliocene, but the climate of the planet is not yet in equilibrium with those high values. It

is possible that a persistence of high carbon dioxide concentrations could result in a return to a globally warm world if it were to increase temperatures and precipitation in high latitudes, and as a consequence cause the tropical thermocline to deepen by a modest amount, a few tens of meters. (Near the date line at the equator, the thermocline is already so deep that its vertical excursions leave surface temperatures unaffected.)

A deepening of the tropical thermocline requires a reduction in the oceanic heat loss in the extratropics (30). However, in certain atmospheric models, warm conditions in high latitudes depend on the atmosphere gaining heat from the oceans (36). This is also the case in the coupled ocean-atmosphere climate model that was recently used to simulate the early Pliocene (37). In that model, the oceanic heat loss in the extratropics is balanced by the gain of heat in the eastern equatorial Pacific. This gain is possible despite higher SSTs in low latitudes because temperature gradients along the equator, and presumably the depth of the equatorial thermocline, do not change significantly. This means that, in the model, maximum SSTs in the western tropical Pacific rise significantly above 30°C. This is inconsistent with observations indicating that at no time in the past 10 million years were SSTs much higher than 30°C. Are the models at fault, or is there a problem with the observations?

More data from the western tropical Pacific (and also from currently warm regions to the west of upwelling zones) are needed to determine the maximum temperatures over the last millions of years, and to determine whether observations of perennial El Niño are robust. If the information available at present should prove accurate, then temperatures in excess of 30°C in some models, and problems in their ability to simulate a perennial El Niño, could be indicative of flaws in the models—for example, in the parameterization of clouds. Models are

Fig. 4. Changes in the zonal SST gradient along the equator (top), the poleward heat transport across a fixed latitude (middle), and the equatorial thermocline depth (bottom) in an idealized ocean GCM as the flux of fresh water onto the surface near the northern boundary of the basin increases. Blue dots correspond to the conditions of today; red dots indicate the equatorial thermocline collapse (33).

they become amplified over the long term (7) when the thermocline shoals (11) and air-sea feedbacks are strengthened.

Discussion

A major factor in the warmth of the early Pliocene was the persistence of El Niño in the

Fig. 5. A sketch of the change (from solid to dashed line) in the thermocline along the equator for (A) an adiabatic, horizontal redistribution of warm water that characterizes the interannual oscillations between El Niño and La Niña, and (B) a slow diabatic increase in the volume of warm water that can lead to a perennial El Niño. An increase in obliquity will correspond to a combination of (B) and (A) because tropical ocean-atmosphere interactions will modify the slope of the thermocline as well. At present, the mean thermocline depth in the equatorial Pacific is ~ 120 m.

designed to reproduce the world of today, but it is unclear how much confidence we should have in simulations of very different climates.

Efforts to predict future global warming could benefit enormously from a better understanding of past climates, especially of the Milankovitch cycles for which the forcing functions are known precisely. The obliquity cycles are of special interest because they started increasing in amplitude around 3 Ma and then changed character again around 1 Ma. Initially, it was thought that the latter change involved a shift of the dominant period from 40 K to 100 K (13). However, recent analyses indicate that the shift could have been from 40 K to multiples of 40 K,

specifically 80 K and 120 K (38). Apparently obliquity continued to play a dominant role, up to the present, in pacing glacial terminations and also in equatorial Pacific variables (21, 39). To determine the relative importance of feedbacks involving ice albedo, tropical ocean-atmosphere interactions, and biogeochemical cycles, it will be valuable to have a detailed description of the obliquity signal over the past several million years, inferred from a synthesis of the diverse measurements (productivity, SST, thermocline depth, ice volume, atmospheric gas concentration, etc.). Explaining the remarkable changes in the climate response to solar forcing that itself did not change significantly is a major challenge for both paleoclimatologists and climate modelers.

References and Notes

- Estimates of the concentration of carbon dioxide in the atmosphere during the early Pliocene range from 340 to 380 ppm (5, 40) to 280 to 300 ppm (41). Today the concentration has been in excess of 330 ppm for only a few decades, and has been elevated above 280 ppm for only 2000 to 3000 years (42).

PALEOCLIMATOLOGY

Looking Way Back for the World's Climate Future

Researchers worry that if they cannot recall the distant climatic past, the world may be condemned to repeat it. And repeating the warmth of the early Pliocene epoch of 3 million to 4 million years ago would be a shocker. With no more

and concludes that humans may already have put the world on a path back to that epoch. "It's a very interesting period to study, a great scientific puzzle," says paleoceanographer David Lea of the University of California

occurring at mid- to high northern latitudes. Those changes might constitute a climatic switch: Throw it one way, and trigger a permanent El Niño in the Pacific Ocean capable of warming the whole world. Throw it the other way, and El Niño and La Niña alternate in a cooler world as they do today.

In an earlier study of Pliocene climate, paleoceanographer Christina Ravelo of UC Santa Cruz, a co-author of this paper, and her colleagues found continuously warm water from one end of the tropical Pacific to the other: the hallmark of an El Niño.

Then about 3 million years ago, the eastern Pacific began cooling, according to their analysis. That set up the warm-in-the-west, cool-in-the-east arrangement that typifies modern conditions. Another analysis of the same deep-sea sediment cores as Ravelo used came up with the opposite Pliocene arrangement: permanent cold in the east

(*Science*, 29 July 2005, p. 687). But Ravelo recently analyzed another kind of paleotemperature record across the Pacific and again found a permanent Pliocene El Niño, which persuades ▶

A coming switch? Atmospheric CO₂ has driven temperature change lately, and the recent CO₂ rise (vertical red line) may be triggering a permanent El Niño (red, inset).

carbon dioxide warming the greenhouse than today, the globe was a good 3°C warmer, and sea level was a whopping 25 meters higher. But how could such a modest stock of greenhouse gas fuel such warming? Unfortunately, no one knows.

On page 1485 of this issue, a group of climate researchers takes a look back at the Pliocene, pulls together models of oceanic and atmospheric behavior under those conditions,

(UC), Santa Barbara. "I like the way they're thinking." But better paleo-data and more realistic modeling will be needed before anyone knows for sure.

The key to understanding Pliocene and possibly future climate, say climate dynamist Alexey Fedorov of Yale University and his colleagues, could be the climate changes

RUSSIAN SCIENCE

Measuring the Hidden Cost of a Pay Raise

MOSCOW—A mandate to increase Russian researchers' pay could have a disastrous impact on long-term science programs, according to institute directors at the Russian Academy of Sciences (RAS). The pay mandate, issued by the government in May and made retroactive to January, aims to boost core salaries in RAS to an average of \$1000 per month. But because the government has not provided a commensurate funding boost, RAS institutes are trying to balance the books with economy measures, including a 2-year moratorium on new equipment purchases. "The recent decision just ruins the development of science," says academician Boris Ioffe, a nuclear physicist at the non-RAS Institute for Theoretical and Experimental Physics in Moscow.

RAS Vice President Alexander Nekipelov announced in May that the academy will cut research staff from 53,000 to 44,000 by 2008, beginning with a 5% reduction this year. This will help pay for some salary increases; for example, a junior researcher's pay may climb

from \$150 to \$300 per month. But the government also placed an indefinite freeze on bonus payments that often go to active researchers in recognition of factors such as scholarly achievement and high-risk work. The net result is that some top scientists will see their pay decline.

"I'm glad that some people working in the academy will get substantially bigger salaries," says Erik Galimov, director of the RAS Vernadsky Institute of Geochemistry and Analytical Chemistry. But he says this will "not solve" the main problem: the declining influx of youthful researchers. His students at Moscow State University often take part-time jobs at the institute, but "when it comes to graduation, they choose jobs with salaries dozens of times higher" than the institute pays. And the mandatory salary boost does not cover engineers, office workers, or financial staff; Galimov predicts that they will become more difficult to retain. If they leave, it would "paralyze the work of the institute," he says.

Ioffe estimates that "the only way" an RAS

institute director can implement the new salary order is to severely slash spending in nonsalary areas. "But you can't do science for nothing," he says. "You have to buy materials, new equipment."

Leonid Bezrukov, deputy head of the RAS Institute for Nuclear Research, regards the equipment purchase moratorium as the main threat. "Modern, expensive facilities are vital for us. You cannot build them on the relatively small" funds available from outside the government budget, he told *Science*. He thinks that his institute will be at a growing disadvantage against laboratories in the West: "We need funds dozens of times more than we have now." There's a risk that the institute may just "drop out," Bezrukov says. His own pay will be reduced by the salary changes; he notes that "all of our active researchers have found themselves in the same situation."

VLADIMIR POKROVSKY

Andrey Allakhverdiv and Vladimir Pokrovsky are writers in Moscow.

Lea that the weight of evidence now favors a Pliocene El Niño over La Niña.

If El Niño ruled the Pliocene, what threw the climatic switch to end its reign some 3 million years ago? To answer that and, conversely, to learn what might switch climate back to Pliocene conditions, Fedorov and his colleagues draw on several modeling studies they have published in recent years. In their scenario, the long-term cooling of the past 50 million years and accompanying drying at high latitudes in the North Atlantic would have cooled surface waters there and made them saltier. Making waters denser would have swelled the river of cold water that sinks into the depths there. That in turn would have increased the volume of cold, deep seawater. Almost all the ocean's water is near freezing, even beneath the tropics; during a permanent El Niño, cold water does not rise to the surface in the eastern Pacific.

But the overlying warm layer would have thinned as the underlying cold water expanded. In the scenario's eastern tropical Pacific, it eventually thinned enough for winds to raise cold water to the surface and break El Niño's grip on the Pacific. That, in turn, would have sharply increased the amount of low-lying clouds reflecting solar heat into space and decreased the amount of water vapor trapping heat in the atmosphere. The breakthrough of tropical cold waters would have thus accelerated global cooling roughly 3 million years ago, when ice first began growing in the north. Today, the strengthening greenhouse seems to be pushing the other way on the switch, warming high latitudes and freshening northern waters with melting ice and more rain.

Nice story, but is it true? "They might be right," says El Niño modeler Amy Clement of the University of Miami in Florida, but so far the modeling has been piecemeal. "You have all the pieces of the puzzle," she says, such as the oceans and atmosphere. But when "you put them together, the result is a lot more complicated than you expect."

Researchers agree that it's urgent to sort through the complications. If there is a climatic switch as described by Fedorov and his colleagues, humans are pushing it harder and harder toward Pliocene conditions. Carbon dioxide emissions are already raising atmospheric levels into the top of the estimated range during the Pliocene, and high northern latitudes are getting warmer and wetter. That alone, say Fedorov and his colleagues, could possibly push Earth back to a permanent, globe-warming El Niño within decades to centuries. In their scenario, all it would take would be a warm surface layer in the eastern Pacific just a few tens of meters thicker than today, and the Pliocene would be back.

PALEONTOLOGY

Ancient 'Reef' Stirs Debate Over Early Signs of Life in Australian Rocks

When paleontologists seek the roots of life, they head to rocks of the Archaean Eon, which range from 3.8 billion to 2.5 billion years old. But it's a tough task: The rocks are so battered and time-worn that any evidence of fossils is greeted with suspicion. For many years, an exception was a familiar-looking structure called a stromatolite, which has a modern analog formed by cyanobacteria. But when computer models suggested that simple chemical reactions and physical forces can mimic stromatolites, those fossils too were cast in doubt.

Now, a new study of ancient stromatolites in western Australia musters evidence that bacteria were indeed thriving 3.4 billion years ago and created an enormous reef. Australian and Canadian researchers argue this week in *Nature* that stromatolites were so diverse and complex that they must have been alive. Some

tute of Technology in Cambridge argued in a *Nature* paper that chemical precipitation, movement of suspended sediment, and other nonbiological factors could create structures resembling at least some stromatolites.

Abigail Allwood, a graduate student at Macquarie University in Sydney, Australia, set out to see just what was in Lowe's rocks. She and colleagues studied and described stromatolites in outcrops across tens of kilometers.

Modern stromatolites are typically mounds, but Allwood found more than seven kinds in the rocks, including some shaped like intricately cusped swales and others like cones. The layers of the latter were thicker on top and thinned down the 50-degree sides, suggesting that colonies of microbes had been growing upward. "The individual grains in them could not have accumulated mechanically because

the slope of the cone is too great," says Stanley Awramik, a stromatolite expert at the University of California, Santa Barbara, who was not involved in the research. In addition, Allwood says, some of the cones had slumped, suggesting they had been covered with a mat of microbes, not a crystalline crust as in mineral formations.

Allwood and her colleagues say it's improbable that physical and chemical processes could have created such a varied, complex geometry. "It's just ridiculous," Allwood says. Runnegar is more cautious. He hasn't yet ruled out other nonbiological processes,

such as currents, but he expects the stromatolites will turn out to be real fossils.

Martin Brasier of Oxford University is less sanguine, arguing that the structures are more likely chemical precipitates. He also objects to the reasoning in the *Nature* paper. "You can't use the argument that complexity is the signature for life," he says. "The extreme variability is what we would expect from a physical mechanism."

A better indicator of life, Brasier argues, would be microfossils with a consistent shape. That would suggest DNA was at work. Brasier and colleagues may have found signs of microfossils in an older portion of the Strelley Pool Chert, which they described online 19 May in the *Philosophical Transactions of the Royal Society B*. "We've put them forward as candidates of interest," he says. Expect a healthy dose of skepticism about their origins, too.

—ERIK STOKSTAD

Fossil or not? New study suggests that features in rocks like this one were created by microbes 3.4 billion years ago.

paleontologists agree, but others remain dubious. Still, the detailed descriptions will be invaluable in constraining computer models of stromatolite growth—and helping determine whether life is needed to explain them, says paleontologist Bruce Runnegar, who directs the NASA Astrobiology Institute in Moffett Field, California. "This paper will be a big step forward in getting it right," he says. Some scientists hope it will also shed light on possible life forms on other planets.

The stromatolites in question were first described by Donald Lowe of Stanford University in 1980, in rocks called the Strelley Pool Chert, some 1400 kilometers northeast of Perth, Australia. Lowe pointed out their resemblance to modern forms but later had doubts. In 1996, John Grotzinger, now at the California Institute of Technology in Pasadena, and Daniel Rothman of the Massachusetts Insti-
